Rheology finds distinct glass and jamming transitions in emulsions

Cong Cao, a,b Jianshan Liao, b Victor Breedveld b and Eric R. Weeks b,*

We study the rheology of monodisperse and bidisperse emulsions with various droplet sizes (1–2 μm diameter). Above a critical volume fraction $\phi_c$, these systems exhibit solid-like behavior and a yield stress can be detected. Previous experiments suggest that for small thermal particles, rheology will see a glass transition at $\phi_c = \phi_g \approx 0.58$; for large athermal systems, rheology will see a jamming transition at $\phi_c = \phi_J \approx 0.64$. However, simulations point out that at the crossover of thermal and athermal regimes, the glass and jamming transitions may both be observed in the same sample. Here we conduct an experiment by shearing four oil-in-water emulsions with a rheometer. We observe both a glass and a jamming transition for our smaller diameter droplets, and only a jamming transition for our larger diameter droplets. The bidisperse sample behaves similarly to the small droplet sample, with two transitions observed. Our rheology data are well-fit by both the Herschel–Bulkley model and the three component model. Based on the fitting parameters, our raw rheological data would not collapse onto a master curve. Our results show that liquid–solid transitions in dispersions are not universal, but depend on particle size.

1 Introduction

Soft amorphous solids include granular materials, foams, and pastes. These are solid in the sense that they possess a yield stress: they elastically (reversibly) support a finite stress below the yield stress, and deform irreversibly if the applied stress exceeds the yield stress. In particular, these materials can typically support their own weight; you can make a pile of sand, a pile of shaving cream, or a pile of paste as well. If you scoop mayonnaise out of a jar, the divot remains for a long time. A granular material such as sand is comprised of solid particles, typically mm or larger sized. A colloidal paste is made from solid particles in a liquid, typically μm size or smaller (small enough to undergo Brownian motion). Foams are gas bubbles in a liquid, stabilized by surfactant molecules to prevent the bubbles from coalescing, and typically with mm or larger sized bubbles. Another soft amorphous solid can be found in emulsions: these are composed of liquid droplets in another immiscible liquid, again with surfactant molecules needed for stabilization, and with droplet sizes ranging from 10 nm up to a few hundred μm. In all of these examples, by diluting the particles the material can lose its solid-like properties: for example, adding water to a pile of shaving cream will eventually change the pile of foam into a puddle with bubbles. More technically, the yield stress for these materials is a function of the volume fraction $\phi$: as the fraction of particles in the volume is decreased, the material flows more easily. For $\phi > \phi_c$, the yield stress becomes nonzero, with critical volume fraction $\phi_c$ depending on details of the system. When these materials undergo the transition from liquid-like to solid-like behavior, these materials share some similarities with glass transition, where a liquid can be changed into an apparent amorphous solid by either increasing $\phi$ (equivalently, density) or decreasing temperature.

Previously Liu, Nagel, and coworkers presented the jamming framework to unify these transitions from liquid into solid. They suggested that in order to change a jammed system into an unjammed one, there are three possible options: increasing the temperature, decreasing the volume fraction, and increasing the applied stress above the yield stress. This can be restated as a conjecture that the yield stress is a universal function of temperature and volume fraction. Focusing just on particulate systems such as the ones mentioned above, one would expect that granular materials, foams, colloids, and emulsions would share a common $\phi_c$ (at least if their particle size distributions are equivalent). However, it has long been noted that the “colloidal glass transition” happens at $\phi_K = 0.58$, and random close packing of granular particles happens at $\phi_{\text{RCP}} = 0.63$ (both situations considering essentially monodisperse hard particles). For an emulsion, a rheology experiment by Mason, Bibette, and Weitz noted that there was evidence of solid-like behavior for $\phi > \phi_g$, and then onset of a higher modulus for $\phi > \phi_{\text{RCP}}$.

The discrepancy in $\phi_c$ was directly addressed in simulations,\textsuperscript{11,12} which showed that rather than $\phi_c$ being a value that changed smoothly from 0.58 to 0.63 depending on conditions, the colloidal glass transition at $\phi_g$ and the jamming transition at $\phi_{RCP}$ are distinct transitions with different physical origins. The rationale is that systems with larger particles are athermal, and thus have a jamming transition, whereas systems with smaller particles are thermal and see a glass transition. For samples of intermediate particle size, two transitions may be possible. A prior study predicted that such phenomena can be observed by measuring rheological performances of dense emulsion samples from 1–10 $\mu$m.\textsuperscript{11} Indeed, the Mason et al. emulsion results\textsuperscript{10} support this prediction qualitatively, using droplets with mean diameter $d = 1.1$ $\mu$m. Overall, the thinking is that a thermal system will have a glass transition at the lower volume fraction $\phi_g$, but that the particles do not need to touch until they reach the higher volume fraction $\phi_{RCP}$. For $\phi > \phi_{RCP}$, particles must deform,\textsuperscript{13–15} which is straightforward for emulsion droplets, so the rheological behavior for these large volume fractions must be dominated by the physics of the particle deformation (for example, surface tension effects for deformed emulsion droplets). In contrast, for $\phi < \phi_{RCP}$ the rheology is determined by the thermally driven glass transition, for suitably thermal particles or droplets.

A series of experiments and simulations have explored the possibility of two distinct transitions, using emulsions\textsuperscript{16–19} and colloidal systems.\textsuperscript{20–23} Most experiments focus on rheological measurements since the yield stress can be easily obtained from a plot of stress as a function of strain.\textsuperscript{24} One set of experiments studied thermosensitive PNIPAM colloidal particles.\textsuperscript{21,22} These samples allow for the volume fraction to be adjusted by changing the temperature. In the second of these two papers (Basu et al.\textsuperscript{22}), they measured the rheological behavior of several samples and compared with their earlier results (Nordstrom et al.\textsuperscript{22}). Between the two papers, the particle diameters ranged from 0.4 to 1.4 $\mu$m, to potentially cover both thermal and athermal sizes; however, the large particles used in the earlier study were softer than the smaller particles used in the later study.\textsuperscript{21} The small particle samples exhibited a glass transition with $\phi_g = 0.61 \pm 0.02$, while the large particle samples had a jamming transition with $\phi_j = 0.635 \pm 0.003$. For these samples, because the volume fraction and particle size are changed at the same time (controlled by temperature), the influence of thermal fluctuations changes by nearly a factor of two from smallest to largest volume fractions studied. Their experiments also used somewhat large steps in volume fraction ($\approx 0.01$ in ref. 22, $\approx 0.05$ in ref. 21), making it challenging to precisely identify the transition points in the latter work.

In the recent work of Dinkgreve et al.,\textsuperscript{19} they study rheological behaviors of athermal emulsions (diameter 3.2 $\mu$m) and compare with earlier published emulsion data\textsuperscript{25} (diameters 0.5–1.5 $\mu$m) and earlier colloid data (diameter 0.37 $\mu$m). The athermal samples had a yield stress for $\phi > \phi_g \approx 0.64$, and the smaller particle samples all had yield stresses for $\phi > \phi_g \approx 0.58$. Nonetheless, they found all samples had similar scaling of their rheological curves, independent of where their transition to a yield stress was found. However, the large and small emulsion samples used different oils (thus with different surface tensions), so it was difficult to directly compare the rheological data between the samples.

In this work we measure rheological behavior for both monodisperse and bidisperse dense emulsions with droplet diameters ranging from 1–2 $\mu$m, using same oil for the droplets, same continuous phase fluid, and same surfactant for all samples. We create our emulsions by using a seed-growth technique.\textsuperscript{26} We use a weighing method to measure our samples’ volume fractions, enabling consistent comparison between samples. We observe that a yield stress appears above $\phi_g = 0.58$ for our samples with smaller droplet diameters ($d \approx 1 \mu$m) and at $\phi_j = 0.63$ for our sample with the largest droplet diameter ($d \approx 2 \mu$m). Using emulsions with identical compositions, and changing the volume fraction while maintaining a constant droplet size, enables us to directly compare samples with identical properties apart from volume fractions; and to compare results of droplets with different diameters but otherwise identical composition. Our results show that indeed two distinct transitions can be seen. Furthermore, we find that a bidisperse sample composed of both small and large droplets has comparable rheological behavior to samples composed only of small droplets.

## 2 Experimental details

### 2.1 Samples

To prepare our 3-(trimethoxysilyl)propyl methacrylate (TPM) samples, we use a seeded-growth method\textsuperscript{26} to obtain TPM emulsions at required size. First we add 1 ml (2 ml for larger emulsions) TPM oil (3-(trimethoxysilyl)propyl methacrylate, 98% – Sigma-Aldrich) into 100 ml pre-made ammonia solution (1 ml 2.8% ammonia diluted with distilled water) in a sealed plastic beaker with a stir bar. We stir the solution at a high speed (350 rpm) to hydrolyze the oil for 20 minutes, then lower the stirring to 200 rpm to condense the oil monomers. After that, every hour we add an additional 1 ml of TPM oil until the droplets grow to our desired size. By diluting the ammonia solution with distilled water (to lower the pH) and changing the amount of added TPM oil, we can tune the final droplet size. (Note that the pH has to be measured prior to injecting the TPM oil.)\textsuperscript{26} In this way we produce 10 ml quantities of emulsions with fairly low polydispersity. We make samples with specific droplet diameters, ranging from 1.0 to 2.1 $\mu$m; see Fig. 1. We then add 0.5 wt% F108 (Synperonic F108 from Sigma-Aldrich) and 5 mM sodium chloride to stabilize our samples.

To accurately measure the sizes of our particles, we polymerize a small portion of each sample by adding 90 $\mu$l of the emulsion solution into preheated 100 ml 0.1 wt% 2,2-azobis (2-methylpropionitrile) (AIBN) solution. We leave this mixture in a 80°C oven for at least 2 hours,\textsuperscript{26} resulting in solidified particles due to polymerization of the TPM oil. We then image these solid particles with a scanning electronic microscope.
(Topcon DS-150F Field Emission SEM); see Fig. 1. We use these images to determine the diameters and polydispersity of our samples. Previous studies suggested that the particles’ volumes will shrink by about 7% after polymerization, corresponding to a 2% reduction in diameter. To confirm that the emulsion droplet diameters are comparable to what we measure with SEM, we use differential dynamic microscopy (DDM) to measure the emulsion droplets’ diameters indirectly. These diameters are within 5% of the SEM results. We will report all diameters based on the SEM data, which has smaller uncertainty even considering the potential 2% systematic error, that is, it is likely that the emulsion droplets are 2% larger than the numbers we report. Our droplets are slightly polydisperse: the standard deviation of their diameters divided by their mean diameter ranges from 0.06 to 0.08. We do not ever observe our droplets to organize into crystalline arrays.

From the initial emulsions, we produce a concentrated stock emulsion by centrifuging our initial samples several times. A series of samples with lower volume fractions are then made by diluting portions of the initial samples with 0.5 wt% F108 and 5 mM sodium chloride in water. To measure the volume fractions, each individual sample is weighted before and after evaporation of water to determine \( f_w \). As in prior work, we correct our volume fractions to take into account the thickness \( h = 17.5 \) nm of the water film between two droplets pressed together near \( \phi_c \), and a linear interpolation to \( h = 5.0 \) nm at \( \phi = 1 \). This adjusts the volume fraction as \( \phi \approx \phi_w(1 + 3h/2a) \) using the measured \( \phi_w \) and droplet radius \( a \); these are the volume fractions reported subsequently in this article. Note that we use the values reported in ref. 25 for \( h \); we do not have an independent measurement of \( h \). Due to the accuracy of our weighing, our volume fractions are correct relative to each other by \( \pm 0.003 \), although the weighing method has an additional systematic uncertainty of \( \pm 0.02 \).

### 2.2 Rheology

Our rheological experiments are conducted using an Anton Paar MC302 rheometer. We study three monodisperse emulsions (\( d_{\text{mean}} = 1.03, 1.16, \) and 2.03 \( \mu m \)) and one bidisperse sample (\( d_{\text{small}} = 1.06 \mu m, d_{\text{large}} = 1.86 \mu m, \) with 1:1 ratio in volume) at room temperature (25 °C). For each sample, we perform a steady shear measurement with a 50 mm cone-plate geometry (truncation height 53 \( \mu m \), cone angle 1.01°). A solvent trap is used to minimize sample evaporation. A 50 mm diameter rough bottom plate is used to eliminate slip at the plate; the cone is not roughened. To provide a reproducible initial condition, we pre-shear all samples with a 10 s\(^{-1} \) shear rate for 30 s and then sit still for another 30 s. All measurements are performed under room temperature. Sedimentation and creaming of particles is negligible within our experimental time scale.

### 3 Results

Fig. 2 shows the rheological curves (stress as a function of strain rate) for two monodisperse samples (panels a and b) and the bidisperse sample (panel c). For all three samples, steady
shear measurements are performed with shears rates ranging from \( \dot{\gamma} = 10^2 \) to \( 10^4 \) s\(^{-1}\). For the lowest volume fractions, we see Newtonian behavior \( (\sigma \sim \dot{\gamma}) \), although with the rheometer tool used the stress dropped below the rheometer torque limit at small strain rates, thus limiting our ability to measure the viscosity. For high volume fractions \( \phi > \phi_c \), we observe a yield stress, signaled by a finite value of stress \( \sigma \) as \( \dot{\gamma} \rightarrow 0 \). The existence of this yield stress is consistent with previous experiments.\(^{1,10,19}\)

The curves of Fig. 2(a and b) show that the transition from solid to liquid happens at different \( \phi \) values for these two different monodisperse samples. For our large droplet sample (\( d_{\text{mean}} = 2.03 \) \( \mu \)m), \( \phi = 0.643 \) has a yield stress and \( \phi = 0.627 \) does not, indicating that the transition volume fraction \( \phi_c \) lies between these two values. This \( \phi_c = 0.635 \pm 0.008 \) is similar to results observed in granular systems.\(^{20}\) For our smaller droplet sample (\( d_{\text{mean}} = 1.16 \) \( \mu \)m), the data indicate \( \phi_c < 0.575 \approx \phi_G \), suggesting that this sample is glassy for \( \phi \geq 0.575 \). Prior work noted that it is hard to accurately compare volume fractions between different publications which used different methods to measure \( \phi \),\(^{28}\) and as mentioned above all of our volume fractions likely have a systematic uncertainty of \( \pm 0.02 \) to account for this. However, the key point is that we use a consistent weight-measuring method for all of our samples with a relative uncertainty of \( \phi \) as \( \pm 0.003 \). In some prior work, due to differing volume fraction measurement techniques, the uncertainty for \( \phi_c \) between different groups was as much as \( \pm 0.06 \), raising the possibility that one group could measure \( \phi_c = 0.58 \) and another group could measure \( \phi_c = 0.63 \) and these could potentially be equivalent.\(^{28}\) Here, since we use a consistent method for determining \( \phi \) across all of our samples, we have strong evidence that the solid-to-liquid transition occurs at lower volume fraction for the smaller particles. This supports the idea that smaller droplets have more significant thermal fluctuations, resulting in a glass transition at a lower volume fraction, whereas the larger droplets are more athermal.\(^{11}\)

All the stress-strain data for \( \phi > \phi_c \) is well fit with the Herschel-Bulkley (HB) model:

\[
\sigma = \sigma_y + k \dot{\gamma}^n
\]  

(1)

These fits are the solid lines in Fig. 2. \( \sigma_y \) is the yield stress, \( k \) is consistency index, and \( n \) is the flow index. The flow index \( n \) is plotted as a function of volume fraction \( \phi \) in Fig. 3(a–d). For all samples, \( n \) is close to 1 for the lower volume fractions \( (\phi \approx \phi_c) \) and then decreases for larger volume fractions, reaching around \( n \approx 0.4–0.5 \) for the largest volume fractions we consider. (We are unaware of any other data set with \( n \) varying so strongly with \( \phi \).) We also show the yield stress \( \sigma_y \) as the + symbols in Fig. 3(m–p). Above, the samples composed of smaller droplets shows a nonzero \( \sigma_y \) starting at \( \phi \approx 0.57 \) [Fig. 3(m and n)] while the sample composed of larger droplets shows a nonzero \( \sigma_y \) starting at \( \phi \approx 0.64 \) [Fig. 3(p)]. Rather than considering the consistency index \( k \) which has unusual units, and anticipating a different fitting model, we rewrite the HB equation as

\[
\sigma = \sigma_y + \sigma_c (\dot{\gamma}/\dot{\gamma}_c)^{0.57} \approx \sigma_y + \sigma_c \left(\frac{\dot{\gamma}}{\dot{\gamma}_c}\right)^{0.57}
\]  

(2)

Here we have replaced the fitting parameter \( k \) with \( \dot{\gamma}_c \), which is a characteristic strain rate scale that will be discussed below.

The different fitting model we next use to describe our data is the "three-component" ("TC") model,\(^{29}\) which has the form:

\[
\sigma = \sigma_y + \sigma_c (\dot{\gamma}/\dot{\gamma}_c)^{0.57} + \eta_b \dot{\gamma}^2
\]

(3)

These fits are indicated by the dashed lines in Fig. 2. Again, \( \sigma_y \) is the yield stress, representing an elastic component for \( \dot{\gamma} \rightarrow 0 \); the circles in Fig. 3(m–p) show that this yield stress is quite similar to the HB fit data (+ symbols in those panels).
The second component is plasticity, with fit parameter $\dot{\gamma}_c$ which is the strain rate at which the contributions to the stress from plasticity and elasticity are equal. The third component is viscous behavior, with $\eta_{bg}$ being the background viscosity—presumably the viscosity of the continuous phase in our emulsion samples, but in practice a third fitting parameter. Fig. 2 shows that for both samples, the TC model and HB model fit our original data nearly equally well, with less than 10% difference in the least squares fitting error.

In addition to the yield stress, the remaining fitting parameters of the TC model are shown in Fig. 3(e-l). For the monodisperse samples with small droplets [Fig. 3(e and f)] we notice that above the jamming transition ($\phi > 0.64$), $\eta_{bg}$ can be set to zero with essentially no change in the quality of the fit.

For situations where the error bar of $\eta_{bg}$ is not zero, we do not plot a point, but rather indicate this by the shading in Fig. 3(e-h). This vanishing of $\eta_{bg}$ shows that viscous behavior plays little role in the high volume fraction samples, at least for the strain rates we can measure. The abrupt disappearance of $\eta_{bg}$ for $\phi > 0.65$ may be related to a jamming transition within the sample. This simplification of eqn (3), with just the first two components, matches the prediction of the kinetic elastoplastic model, which appropriately is expected to apply for jammed materials.31,32 This rheological behavior has often been seen in high volume fraction foams; see ref. 33 for a review. It includes $\dot{\gamma}_c$ as a function of $\phi$ in Fig. 3(i and j): for $\phi < 0.61$, the uncertainty of $\dot{\gamma}_c$ is large, essentially setting the contribution of the plastic term to zero. Again, where the uncertainty of $\dot{\gamma}_c$ does not exclude $\infty$, we do not plot a point, but rather indicate this by the shading in Fig. 3(i, j and l). In this case the TC model (eqn (3)) reduces to the Bingham model. For the HB model, $\dot{\gamma}_c$ is always finite. For the two samples with small droplets, Fig. 3(e, f, i and j) show that there is a range of $\phi$ for which both plastic and viscous behavior coexist; both terms are needed to describe the stress/strain data.

For the sample with larger droplets (right-most column of Fig. 3), we also observe these abrupt changes in $\dot{\gamma}_c$ and $\eta_{bg}$. Interestingly, both of these changes happen at around same volume fraction $\phi \approx 0.69$, suggesting there is no volume fraction at which both plastic and viscous behaviors are observable in this athermal sample. By comparing the HB and TC fitting parameters, we notice that both models suggest plastic behavior dominates at high volume fractions ($n \approx 0.5$ and $\eta_{bg} = 0$) and viscous behavior plays a more important role for samples close to the glass transition ($n \approx 1$ and $\dot{\gamma}_c \to \infty$).

Finally, for the bidisperse sample (red data, third column of Fig. 3) we see behavior mostly similar to the two samples with smaller droplets. The similarities include that $\eta_{bg}$ vanishes at $\phi \approx 0.63$, and $\sigma_y$ is nonzero for $\phi \approx 0.59$. We do not see any transition when plotting the TC fit parameter $\dot{\gamma}_c$ as a function of $\phi$. In our experiment, for the small droplet diameter samples (1.03, 1.16 $\mu$m), the yield stress only weakly depends on $\phi$ for high $\phi$. A more significant change in $\sigma_y$ is seen around $\phi \approx 0.6$, although $\sigma_y$ still remains nonzero until $\phi \approx 0.58$. This qualitatively resembles Ikeda et al.’s “glass” simulation data shown in Fig. 4(b). In contrast, our large diameter droplet sample (2.03 $\mu$m) has a yield stress which starts to decrease rapidly at higher volume fraction (at around $\phi \approx 0.70$), and $\sigma_y$ disappears at $\phi \approx 0.643$. These results show that the critical solid-to-liquid transition happens at different volume fractions depending on particles’ size. For the simulations, the $\sigma_y$ data overlap for $\phi \approx 0.66$ whereas for our experiment, overlap is only seen for $\phi \approx 0.70$.

To characterize the difference between “large athermal” and “small thermal” particles, Ikeda et al. considered the effective temperature $T_{eff} = k_BT_{a} / \varepsilon$, where $\varepsilon$ represents an energy scale related to the particle stiffness.11 This effective temperature characterizes how easy it is for thermal fluctuations to deform particles, thus allowing them to slip past one another. In our experiment, we measure the TPM surface tension using the pendant drop method (Dropometer, made by Dropletlab). We measure the surface tension to be $\Sigma = 3$ mN m$^{-1}$, which is

![Fig. 4](https://example.com/fig4.png) (a) The yield stress $\sigma_y$ as a function of volume fraction $\phi$ for our experimental data; each set of data is labeled by the mean droplet diameter. The red asterisk data are for the bidisperse sample, labeled by the two mean droplet diameters. The effective temperature ranges from $T_{eff} = 5 \times 10^{-6}$ for the $d = 1.03 \mu$m sample to $1.3 \times 10^{-6}$ for the $d = 2.03 \mu$m sample; see text for details. The dashed lines are exponential fit curves $\sigma_y = \sigma_y e^{-\phi}$, with $\sigma_y = 3 \times 10^{-17}$ Pa, $C = 60$ for small particles and $\sigma_y = 2 \times 10^{-21}$ Pa, $C = 70$ for the larger particles.34 (b) Simulation results from ref. 11. As $\phi$ is decreased, the system goes through the jamming transition at around $\phi \approx 0.64$, with an abrupt drop in yield stress. After that, it will stay in a glassy regime, with only a moderate decrease of the yield stress until it reaches the glass transition point $\phi_{tg} \approx 0.58$, at which point the yield stress vanishes.11 The red dashed line represents the $T = 0$ limit (for large, athermal particles). For the black curves, the effective temperature varies by factors of ten, ranging from the top black curve (‘Fluid’, $T_{eff} = 5 \times 10^{-6}$) to the bottom black curve (‘Glass’, $T_{eff} = 10^{-7}$). $\sigma_y$ has been nondimensionalized in a way similar to our mechanical yield stress [see Fig. 5(b)]. (Reprinted figure with permission from Ikeda, Berthier, and Sollich, Phys. Rev. Lett., 2012, 109, 018301.11 Copyright 2012 by the American Physical Society.).
dominate the rheological behavior. This seems sensible: the small droplets are more effective in creating droplet surfaces and therefore impose motion. The Péclet number is defined as $Pe = \frac{g}{T}$, where $g$ is the viscosity of the continuous phase solvent, $k_B$ is the Boltzmann constant, $T$ is the experimental temperature (room temperature), and $d$ is the diameter of our particles.\textsuperscript{12,21} It represents how important the shear motions are compared to thermal motion: the larger the Péclét number, the less thermal the system is. In our experiments, we changed droplet sizes by a factor of 2, which leads to a factor of 8 change in $Pe$. For our small samples ($d = 1.03$ and $1.16$ $\mu$m samples), $Pe = 2 \times 10^{-6}$-$2 \times 10^2$, which covers a similar range as Basu’s experiment.\textsuperscript{21} For our large sample ($d = 2.03$ $\mu$m), $Pe = 1.6 \times 10^{-5}$-$1.6 \times 10^1$. Having $Pe \sim O(1)$ suggests thermal motion will play a role in our experiments,\textsuperscript{12} although with a caveat: our samples, at high volume fraction, do not freely diffuse. If we were to use the modified Péclét number $Pe^*$ based on the effective diffusivity, we would find $Pe^* \sim (10^{-10})Pe$,\textsuperscript{36} implying more athermal behavior.

As noted above, the yield stress of our bidisperse sample with droplet diameters $1.06$ $\mu$m and $1.86$ $\mu$m behave similarly to the two small droplet size monodisperse samples [Fig. 4(a)]. This suggests that in a bidisperse sample, the small droplets dominate the rheological behavior. This seems sensible: the glass transition should be induced by the thermal motion of the small particles. In our bidisperse sample, the two droplets have equal volume fractions within the sample; it is an open question as to how much of the smaller droplet is necessary to see a glass transition.

For samples with $\phi > \phi_c$, we fit the yield stress data to an exponential growth model; see the straight lines in Fig. 4(a). These fits are just to the data where the growth of $\sigma_g$ appears roughly linear on this semilog plot, so $0.58 \leq \phi \leq 0.64$ for the small diameter emulsion sample and $0.64 \leq \phi \leq 0.70$ for the large diameter emulsion sample. In our experiments, the yield stress grows with volume fraction more strongly when increasing particle’s diameter, from $\sigma_g \sim C_1e^{0.006}$ to $\sigma_g \sim C_2e^{0.006}$. These fits are consistent with the entropic barrier hopping model suggested by Kobelev and Schweizer,\textsuperscript{34} despite slight differences in the exponent $(\gamma_g \sim e^{0.006}$ for them). Consistent with their prediction, the larger the particles are, the more abruptly $\sigma_g$ will decrease with $\phi$. The prefactors have values $C_1 = 3 \times 10^{-17}$ and $C_2 = 2 \times 10^{-21}$, and are not assigned any physical meaning.\textsuperscript{34}

To further understand how the yield stress changes with volume fraction, we consider three additional data sets from prior literature. Two data sets are taken from Mason, Bibette, and Weitz who studied silicon oil in water emulsions using both steady and oscillatory shear.\textsuperscript{25} These emulsions were stabilized by sodium dodecyl sulfate (SDS) and employed the fractionation method to produce fairly monodisperse samples with droplet diameters between $0.5 \mu$m to $1.5 \mu$m; the surface tension was $\Sigma = 9.8$ $mN m^{-1}$. They investigated the yield stress of their samples. They concluded that their samples had a size-independent transition which they called a glass transition at $\phi = 0.58$. The third data set is from Dinkgreve \textit{et al.}\textsuperscript{17-19} who studied castor oil in water emulsions using steady shear, similar to our experiments. Their samples had a larger mean droplet diameter, $d = 3.2$ $\mu$m, and the surface tension was $1.5$ $mN m^{-1}$; the droplet size was intentionally chosen to be in the athermal regime. The large athermal droplets had a liquid-to-solid jamming transition at $\phi = 0.64$. In ref. 19 they also examined the earlier data of Mason, Bibette, and Weitz,\textsuperscript{25} and found that all the data (both thermal and athermal droplet sizes) fit well into an identical master curve for $\phi > \phi_c$, albeit with different $\phi_c$ values for the different droplet sizes.

We compare these prior data sets to our emulsion data Fig. 5. To better understand how thermal motion and particle deformation affect our system, here we define a nondimensional thermal yield stress $\sigma_g = \sigma_gd^3/k_BT$ and a nondimensional yield stress $\sigma_0 = \sigma_0d/\Sigma$.\textsuperscript{12} Our data are the red symbols, and the literature data are the blue symbols, as indicated by the legend in Fig. 5(b). In all cases, the effective temperature is small ($k_BT/e \ll 1$). Neither the thermal yield stress [Fig. 5(a)] nor the mechanical yield stress [Fig. 5(b)] collapse the data perfectly.

The thermal yield stress comparison is based on a simple idea, that the modulus of a solid should scale as $k_BT/d^2$ for a sample made of components with inter-particle distance $d$\textsuperscript{12,37} -- indeed, this is the basic reason that “soft matter” composed of micron-sized objects is softer than “hard matter” made of atoms with nanometer spacing. This also should be the relevant yield stress for the glass transition, as at $\phi = \phi_c \approx 0.58$, the droplets do...
The surface energy greatly exceeds the thermal energy and in general the deformation gives rise to the yield stress. The yield stress is due to the surface tension for volume fractions that the yield stress is due to the surface tension for volume fractions, while for samples without a glass transition, we do not measure a nonzero yield stress until \( \phi > \phi_g \). The glass transition is observable in our samples with smaller droplet diameters \( (d \approx 1 \mu m) \), whereas our sample with the largest diameter \( (d = 2.03 \mu m) \) is the case with only a jamming transition. We additionally find evidence that our samples with a glass transition also have a jamming transition at \( \phi_1 \). This is marked by a dramatic rise of the yield stress by about two orders of magnitude and a disappearance of the viscous component from the three-component (TC) model fit (eqn (3)). Intriguingly, the “athermal” sample with only a jamming transition shows a transition of a different sort around \( \phi \approx 0.70 \), where the TC model fit transitions from needing only a viscous component \( (\phi < 0.70) \) to needing only a plastic component \( (\phi > 0.70) \). Of course, it is possible that the apparently missing components simply mean that we cannot measure them with the resolution of our rheometer; in particular, the viscous component may simply have moved to shear rates faster than our ability to measure, as certainly the limiting behavior for \( \gamma \to \infty \) must be viscous.

The key advantages of our experiments are that we use one type of particle for all measurements, emulsion droplets of the same oil in water, so that the particle interaction does not change as we change the droplet size; we have a consistent means of measuring the volume fraction across all samples; and we vary volume fraction while keeping our droplet size fixed (in contrast to hydrogel particles, for example ref. 21).

4 Conclusions

We have studied the rheological behavior of concentrated emulsions over a range of droplet sizes and volume fractions, finding evidence of both a thermal-like glass transition at \( \phi_g \approx 0.58 \) and an athermal-like jamming transition at \( \phi_1 \approx 0.64 \). For the samples with a glass transition, the yield stress becomes nonzero for \( \phi > \phi_g \), while for samples without a glass transition, we do not measure a nonzero yield stress until \( \phi > \phi_g \). The glass transition is observable in our samples with smaller droplet diameters \( (d \approx 1 \mu m) \), whereas our sample with the largest diameter \( (d = 2.03 \mu m) \) is the case with only a jamming transition. We additionally find evidence that our samples with a glass transition also have a jamming transition at \( \phi_1 \). This is marked by a dramatic rise of the yield stress by about two orders of magnitude and a disappearance of the viscous component from the three-component (TC) model fit (eqn (3)). Intriguingly, the “athermal” sample with only a jamming transition shows a transition of a different sort around \( \phi \approx 0.70 \), where the TC model fit transitions from needing only a viscous component \( (\phi < 0.70) \) to needing only a plastic component \( (\phi > 0.70) \). Of course, it is possible that the apparently missing components simply mean that we cannot measure them with the resolution of our rheometer; in particular, the viscous component may simply have moved to shear rates faster than our ability to measure, as certainly the limiting behavior for \( \gamma \to \infty \) must be viscous.

The key advantages of our experiments are that we use one type of particle for all measurements, emulsion droplets of the same oil in water, so that the particle interaction does not change as we change the droplet size; we have a consistent means of measuring the volume fraction across all samples; and we vary volume fraction while keeping our droplet size fixed (in contrast to hydrogel particles, for example ref. 21).
A concern might be that we do not have a sample with only a glass transition, and not a jamming transition. However, as per Fig. 4(b), our samples have deformable droplets and the volume fraction can always be increased well above $\phi_1$, and thus we should always see a jamming transition around $\phi_j$ once the droplets begin to deform – which indeed is what is suggested by our data in Fig. 4(a).

Prior simulations by Olsson and Teitel found that the rheological curves for soft particles near jamming could be rescaled onto master curves (one curve for jammed samples, a second curve for unjammed samples; given that our data are well-fit with both the HB and TC models – but with varying power law exponent $n$ (HB model) or other fitting coefficients (TC model), we have not presented a data collapse of the raw rheological data shown in Fig. 2. To the extent that the HB and TC models are reasonable fits, the dependence of the fitting parameters on $\phi$ shows that our data do not follow a master curve. This is in contrast with some prior experimental work with hydrogel particles, for which $n \approx 0.5$ was essentially constant, allowing for a good data collapse. In contrast to our work, these soft hydrogel particles only had one transition (probably a glass transition) as their volume fraction was increased, even to well above $\phi_{BGP}$. The range of Pelet number was similar between their work and our work, although our largest particles reach a Pe more than an order of magnitude over a similar range of $f$.

Interestingly, our yield stresses increase by three orders of magnitude as we increase their polymeric nature. Nonetheless one might expect that at $\phi_{BGP}$ the hydrogel particles would not yet be deformed and that their rheological behavior would change for $\phi \geq \phi_j$ after deformations are mandatory; this was not seen. Another interesting difference is that our yield stresses increase by three to four orders of magnitude as we increase $\phi$ (see for example Fig. 4), in agreement with the early work of Mason and Weitz, whereas the hydrogel particles saw an increase of only one order of magnitude over a similar range of $\phi$. Comparing with our work, these interesting differences suggest that liquid-to-solid transitions as the volume fraction is increased may be non-universal in ways beyond the size-dependent glass transition/jamming transition distinction; that the particle type (hard colloid, soft hydrogel, emulsion droplet) matters as well. A plausible other explanation is that if similar rheological studies were done with larger hydrogel particles one could see a jamming transition.
